

Basin Overview November 2003

Upper Western Shore

Restoring the Bay: The Land-Water Connection

The Upper Western Shore, like other tributaries to the Chesapeake Bay, is degraded by nutrient and sediment pollution harming aquatic life. Excess nutrients and sediments are the primary sources of pollution in the Chesapeake Bay. Nutrients occur naturally in soil, animal waste, plants, and the atmosphere; but in the Chesapeake Bay watershed, urbanization and farming have increased nutrient loads to unhealthy levels. These nutrients – nitrogen and phosphorus – promote the growth of algae, which in turn, blocks sunlight from reaching underwater grasses and reduces dissolved oxygen and suitable habitat for aquatic life.

The Upper Western Shore Basin

The Upper Western Shore basin drains approximately 920 square miles of land, including all of Harford County and portions of Carroll, Baltimore, and Cecil Counties.

Larger water bodies in the basin include the Susquehanna River, Bush River, Gunpowder River, Little Gunpowder Falls, Deer and Octoraro Creeks, Conowingo Pool, Loch Raven and Pretty-Boy Reservoirs, and tidal embayments in the lower portions of the basin, including Middle River.

The Upper Western Shore, along with all tributary basins in the Chesapeake, contribute to and are impacted by nutrient pollution. Nutrient pollution can be divided into two major categories – point sources (pollution that comes from a single, definable location, such as a wastewater treatment plant or industrial discharge) and non-point sources (pollution that cannot be attributed to a clearly identifiable, specific physical location, such as runoff from land and atmospheric deposition). Runoff from different land uses, point sources, and atmospheric deposition are the major sources of nutrients within the Bay watershed.

In the Upper Western Shore basin, land use is

primarily agricultural and forests in addition to large amounts of developed land. Approximately 33% of the nitrogen and phosphorus pollutants come from agriculture sources, while urban non-point sources contribute 17% of the nitrogen and 29% of the phosphorus and point source loadings which account for 16% and 21% of the nitrogen and phosphorus, respectively. Forest and wetlands are a land use that releases few nutrients to rivers and the Bay. Baywide, approximately 33% of nitrogen loads come from atmospheric sources; however, this figure varies from basin to basin and is included in land based loads.

A Work in Progress

Maryland has been working since the first Chesapeake Bay Agreement was signed in 1983 to reduce nutrient pollution to the Chesapeake Bay. Since 1985, wastewater treatment plants, farmers, and others have achieved significant nitrogen and phosphorus reductions. Nitrogen loads in the Upper Western Shore basin have been reduced 20% from 5.34 to 4.27 million pounds a year since 1985, and phosphorus loads have been reduced 33% from .40 to .26 million pounds.

Large portions of these reductions were achieved through point source reductions in addition to agricultural

Upper Western Shore Basin Nutrient Goals

*Updated 2002 Progress information available soon

best management practices (BMPs). These are practices that provide the most effective and practicable means of controlling pollutants, such as nutrient management or cover crops. In the Upper Western Shore basin, nitrogen from agriculture dropped 37% and phosphorus decreased 50%, while nitrogen loads and phosphorus point source contributions dropped 25% and 38%, respectively. Loading from urban non-point sources decreased by 9% for nitrogen and 26% for phosphorus between 1985 and 2000.

Goals for a Healthy Bay

In 2000, the Chesapeake Bay Program partners – Maryland, Virginia, Pennsylvania, the District of Columbia, the U.S. Environmental Protection Agency, and the Chesapeake Bay Commission – signed *Chesapeake 2000*, a new agreement designed to protect and restore living resources, vital habitats, and water quality in the Bay and its watershed. Key parts of this agreement include developing new nutrient and sediment goals for the Bay and its tidal tributaries based on the needs of living resources and revising the Tributary Strategies to achieve these new goals.

The revised nutrient caps for the Upper Western Shore basin are 2.06 million pounds of nitrogen and .12 million pounds of phosphorus.

In the spring of 2003, the Chesapeake Bay Program finished developing water quality criteria that identify the levels of dissolved oxygen, water clarity, and chlorophyll (algae) that are needed to support healthy populations of Bay living resources. The Chesapeake Bay Program used computer models to estimate the amount of nitrogen and phosphorus loads (also called loading caps) that can enter the Bay while achieving these water quality criteria. These loads were allocated to each tributary basin and state. As a result, each basin will have nutrient reductions to be achieved in order to reach their nutrient loading cap.

Water Quality

Monitoring data for the Upper Western Shore show trends from 1985 – 2000. Over this period, nitrogen and phosphorus levels improved in the tidal portion of Middle River, but phosphorus levels increased (worsened) in the Bush River. Algal levels are poor at all of the tidal stations in the Upper Western Shore, indicating that further nutrient reductions are needed to improve water quality.

Living Resources in the Upper Western Shore

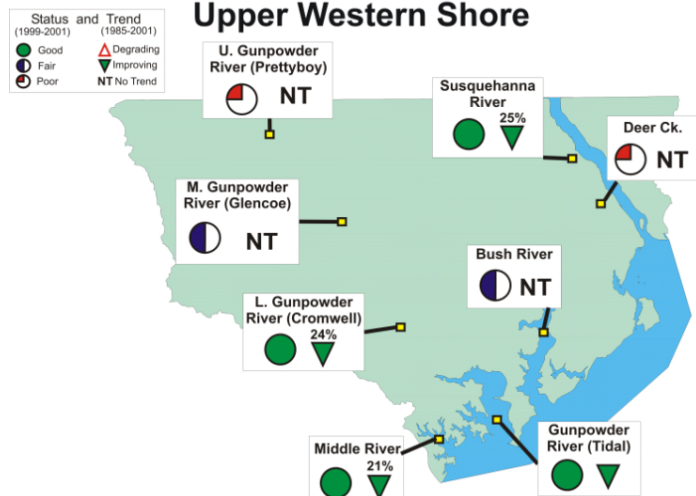

The Upper Western Shore watershed provides habitat for many species of aquatic and terrestrial life. The basin supports more than 75 species of fish in its freshwater streams and brackish waters, including striped bass, white and yellow perch, trout, and large and smallmouth bass.

Local Benefits

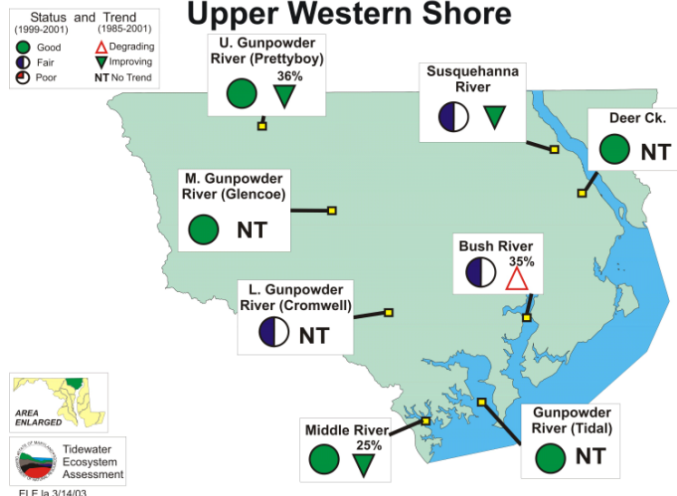

By addressing nutrient and sediment pollution in the Upper Western Shore basin there will be both local and downstream advantages. The result will be a decrease in algal production that will aid in the return of underwater grasses and improved habitat.

For nontidal areas, the Maryland Biological Stream Survey (MBSS) provides a picture of overall ecological stream health (since 1995 in this basin). Data, such as measures of the variety of species, pollution sensitivity, and proportion of exotic species, are collected for each stream. These data are combined into one overall value, or index of health, for the streams in the Upper Western Shore watershed which is referred to as an Index of Biotic Integrity (IBI). By using this index, complex ecological information can be summarized and stream health can be rated as good, fair, poor, or very

Total Nitrogen Concentrations: Upper Western Shore

Total Phosphorus Concentrations: Upper Western Shore

poor. Streams rated good or fair by the index are considered healthy compared to reference streams, while streams rated poor or very poor are considered unhealthy.

In the Gunpowder and Susquehanna Rivers, 35% of the monitoring sites were rated as having a good Index of Biotic Integrity scores. The Bush River had 42% of sites classified as good. Across the basin, many streambanks are susceptible to erosion. In the Gunpowder River, almost 80% of the streambanks were rated as poor as compared to 30% in the Susquehanna River and 50% in the Bush River.

Addressing the quality of the streams will improve local habitat quality and support the Bay's critical natural resources. Healthy local streams and rivers do not just serve as a recreational asset to the local community but often translate into an increased quality of life and local economic benefits.

Downstream Benefits

Restoration efforts in the Upper Western Shore will be felt elsewhere. By achieving the nutrient goals, and addressing sediment in the Upper Western Shore basin, we expect to see decreased algal production downstream, better habitat, and a

resurgence of underwater grasses. The following is a description of living resource challenges and goals for the mainstem and tidal areas of the Chesapeake Bay Watershed.

Bay Grasses

Underwater grasses, or submerged aquatic vegetation, play an important ecological role to the Chesapeake Bay environment. They provide food, refuge and nursery habitat for many waterfowl, fish,

shellfish, and invertebrates, and produce oxygen in the water column. These grasses also filter and trap sediment that cloud the water and bury bottom-dwelling organisms, such as oysters; provide shoreline erosion protection by slowing down wave action; and remove excess nutrients that could fuel unwanted growth of algae in the surrounding waters.

Submerged aquatic vegetation had largely vanished in the Bay by

the 1970s, primarily due to poor water quality. Over the past decade, improvements in water quality have led to a modest resurgence in underwater grasses in some parts of the Bay. In 2000, underwater grasses covered about 69,000 acres in the Bay. In 2003, the Chesapeake Bay Program set a new goal for underwater grasses of 185,000 acres Baywide. This was based in part on the amount of grasses that would return once we achieve the new nutrient reduction goal.

Blue Crabs

The blue crab is one of the most important species harvested in the Bay. It has the highest value of any commercial fishery and supports a recreational fishery of significant, but undetermined, value. Due to loss of habitat and harvest pressure, however, the abundance of mature female crabs is at near historic lows. The *Chesapeake 2000 Agreement* calls for the Bay partners to “manage the blue crab fishery to restore a healthy spawning biomass, size, and age structure.” To achieve this, Maryland and Virginia have committed to reduce harvest pressure on blue crabs by 15% compared to the harvests of 1997 through 1999.

Restoring underwater grasses will be an important step in restoring blue crab populations. During the 1970s and 1980s, the widespread disappearance of underwater grasses resulted in a severe loss of important crab habitat and nursery areas, primarily for females and crabs in the molting stage. Bay scientists have found that 30 times more juvenile crabs were found in areas with Bay grasses than in areas without.

Oysters

Over-harvesting, dwindling habitat, pollution, and diseases (such as Dermo and MSX) have caused a severe decline in oysters throughout the Chesapeake Bay over the last century. Since the 1950s, harvests have fallen Baywide from 35 million pounds to below 3 million pounds. In addition to their fisheries value, oysters are critical to the Bay's ecosystem. They provide habitat for many Bay species and help improve water clarity by filtering

algae and sediment from the water.

The *Chesapeake 2000 Agreement* commits to increasing native oysters tenfold by 2010. The Oyster Restoration Strategy, which was developed to support the agreement, focuses on rehabilitating oyster habitat, much of which is degraded by silt and nearly barren. In addition to improving habitat, the strategy aims to increase the oyster population by the construction of a Baywide network of non-harvest sanctuary areas. Up to 250 such areas have been suggested throughout the Bay so far. Protected from harvesting, it is hoped that some of the oysters in these sanctuaries will survive disease and enhance the Bay's oyster population.

Tools for Change

Maryland's Tributary Teams are leading the revision of their Tributary Strategies – watershed-based plans to achieve the nutrient and sediment goals within each of the state's 10 tributary basins. Restoring the Upper Western Shore will require the active involvement of all watershed residents. Strategies for the Upper Western Shore basin will be drawn from an array of measures to reduce the amounts of nutrients from wastewater treatment plants and agricultural, urban, and suburban lands. Protection of forests and wetlands will help prevent increases in nitrogen and phosphorus loads.

The Next Steps

Over the coming months, the Upper Western Shore Tributary Team and Maryland's Departments of Natural Resources, Environment, Agriculture, and Planning will work closely with residents of the basin to identify best management practices that can be applied in the watershed to reduce nutrient pollution and restore habitat.

These practices will be summarized in a Tributary Strategy for the basin. Funds to implement this strategy will be sought from federal, state, and local governments. Private landowners and other watershed residents will also contribute. While implementation may not be complete by the target date of 2010, every effort will be made to reach the water quality goals by that date.

With input from the 1st round of public meetings in June 2003, the Tributary Strategy for the Upper Western Shore basin was drafted this summer and fall by the team and the Tributary Strategies Development Workgroup. This workgroup worked closely with state and local governments, team members, local constituents and other stakeholder groups. The working draft of the document will be available for review, and a second round of public meetings is planned for December 2003 for public review of the strategies.
